

Introduction

- The sensory consequences of voluntary actions are typically perceived as weaker than the same sensory events that are externally generated.
- Predicted sensory signal is removed from the perceived sensation following one's own action, enhancing the relative intensity of externally produced sensory events.
- Sensorimotor attenuation has been suggested to be mediated by a prediction mechanism, whereby an 'efference copy' of the motor command is used to predict its sensory consequences.
- Previous studies suggested sensorimotor attenuation relies on brain signals related to preparation for action, originating from areas upstream to primary motor cortex.

What are the brain areas related to sensorimotor attenuation?

Methods

Subjects: n=146, aged 18-90 (55±19)

Force Matching:

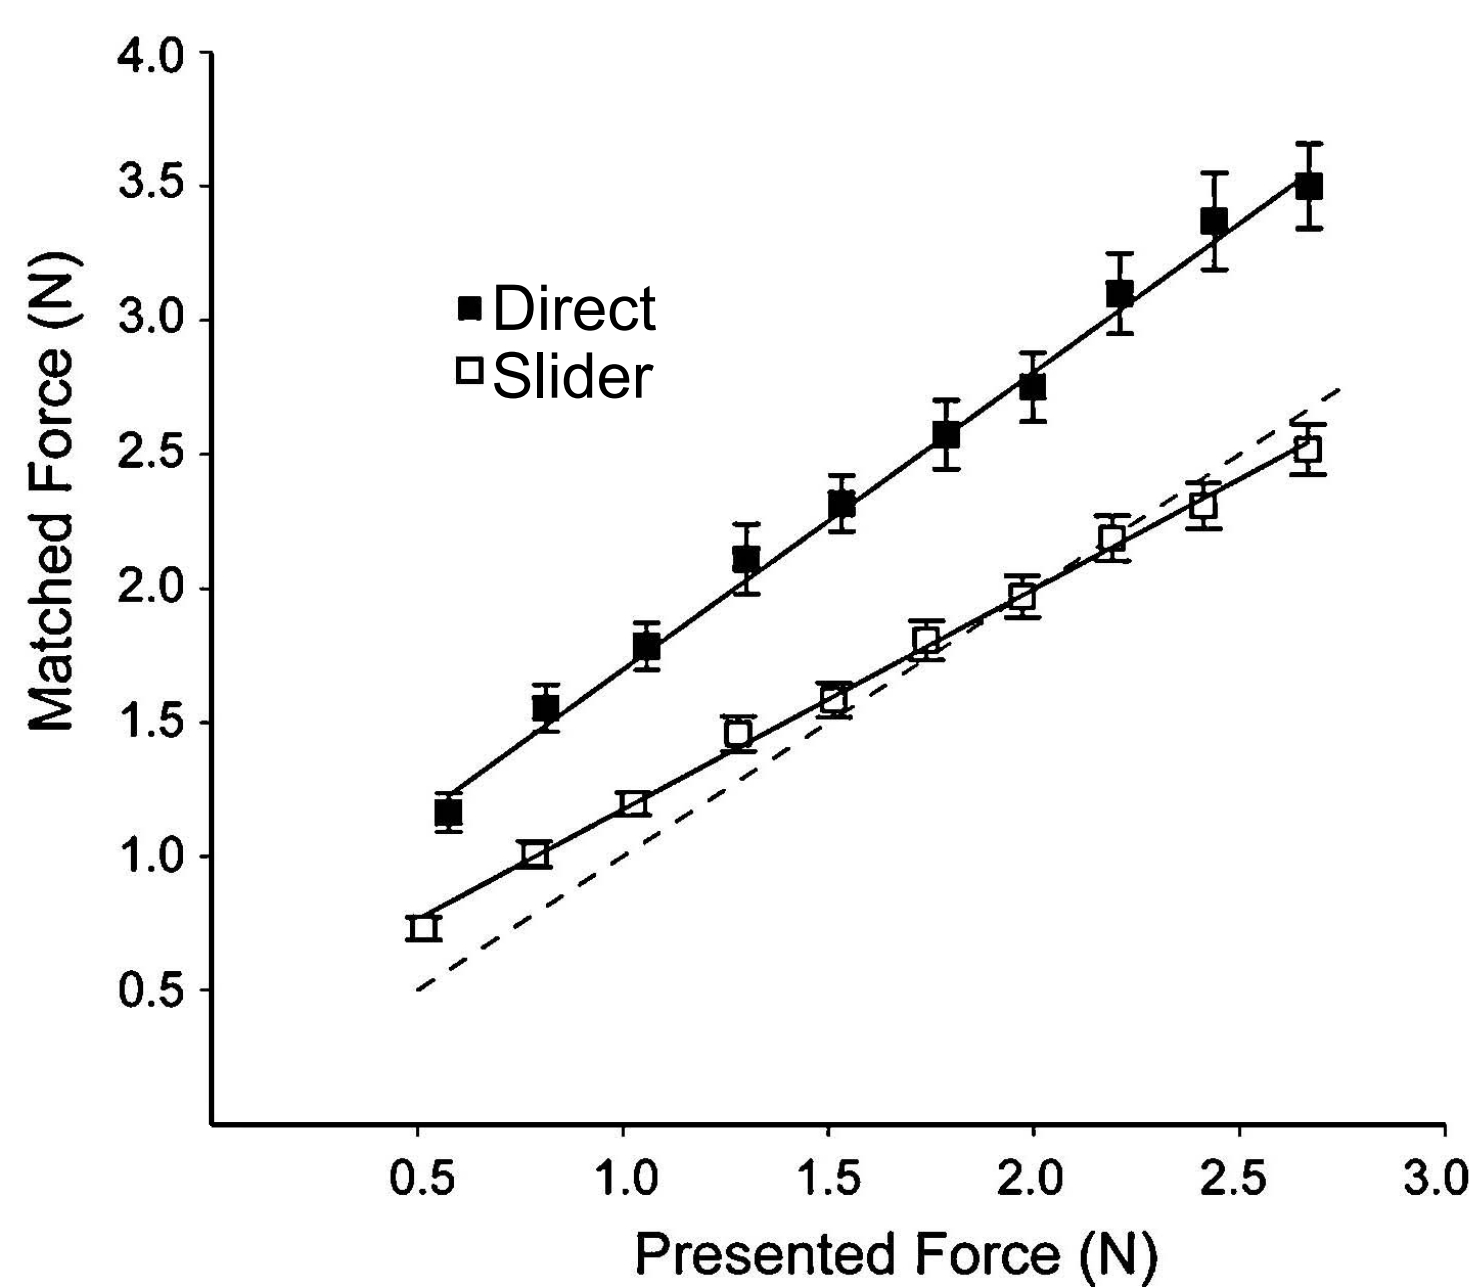

MRI: Siemens Trio 3T

MPRAGE; 1 mm isotropic for Voxel-Based Morphometry with SPM8

Results

Typical individual subject data

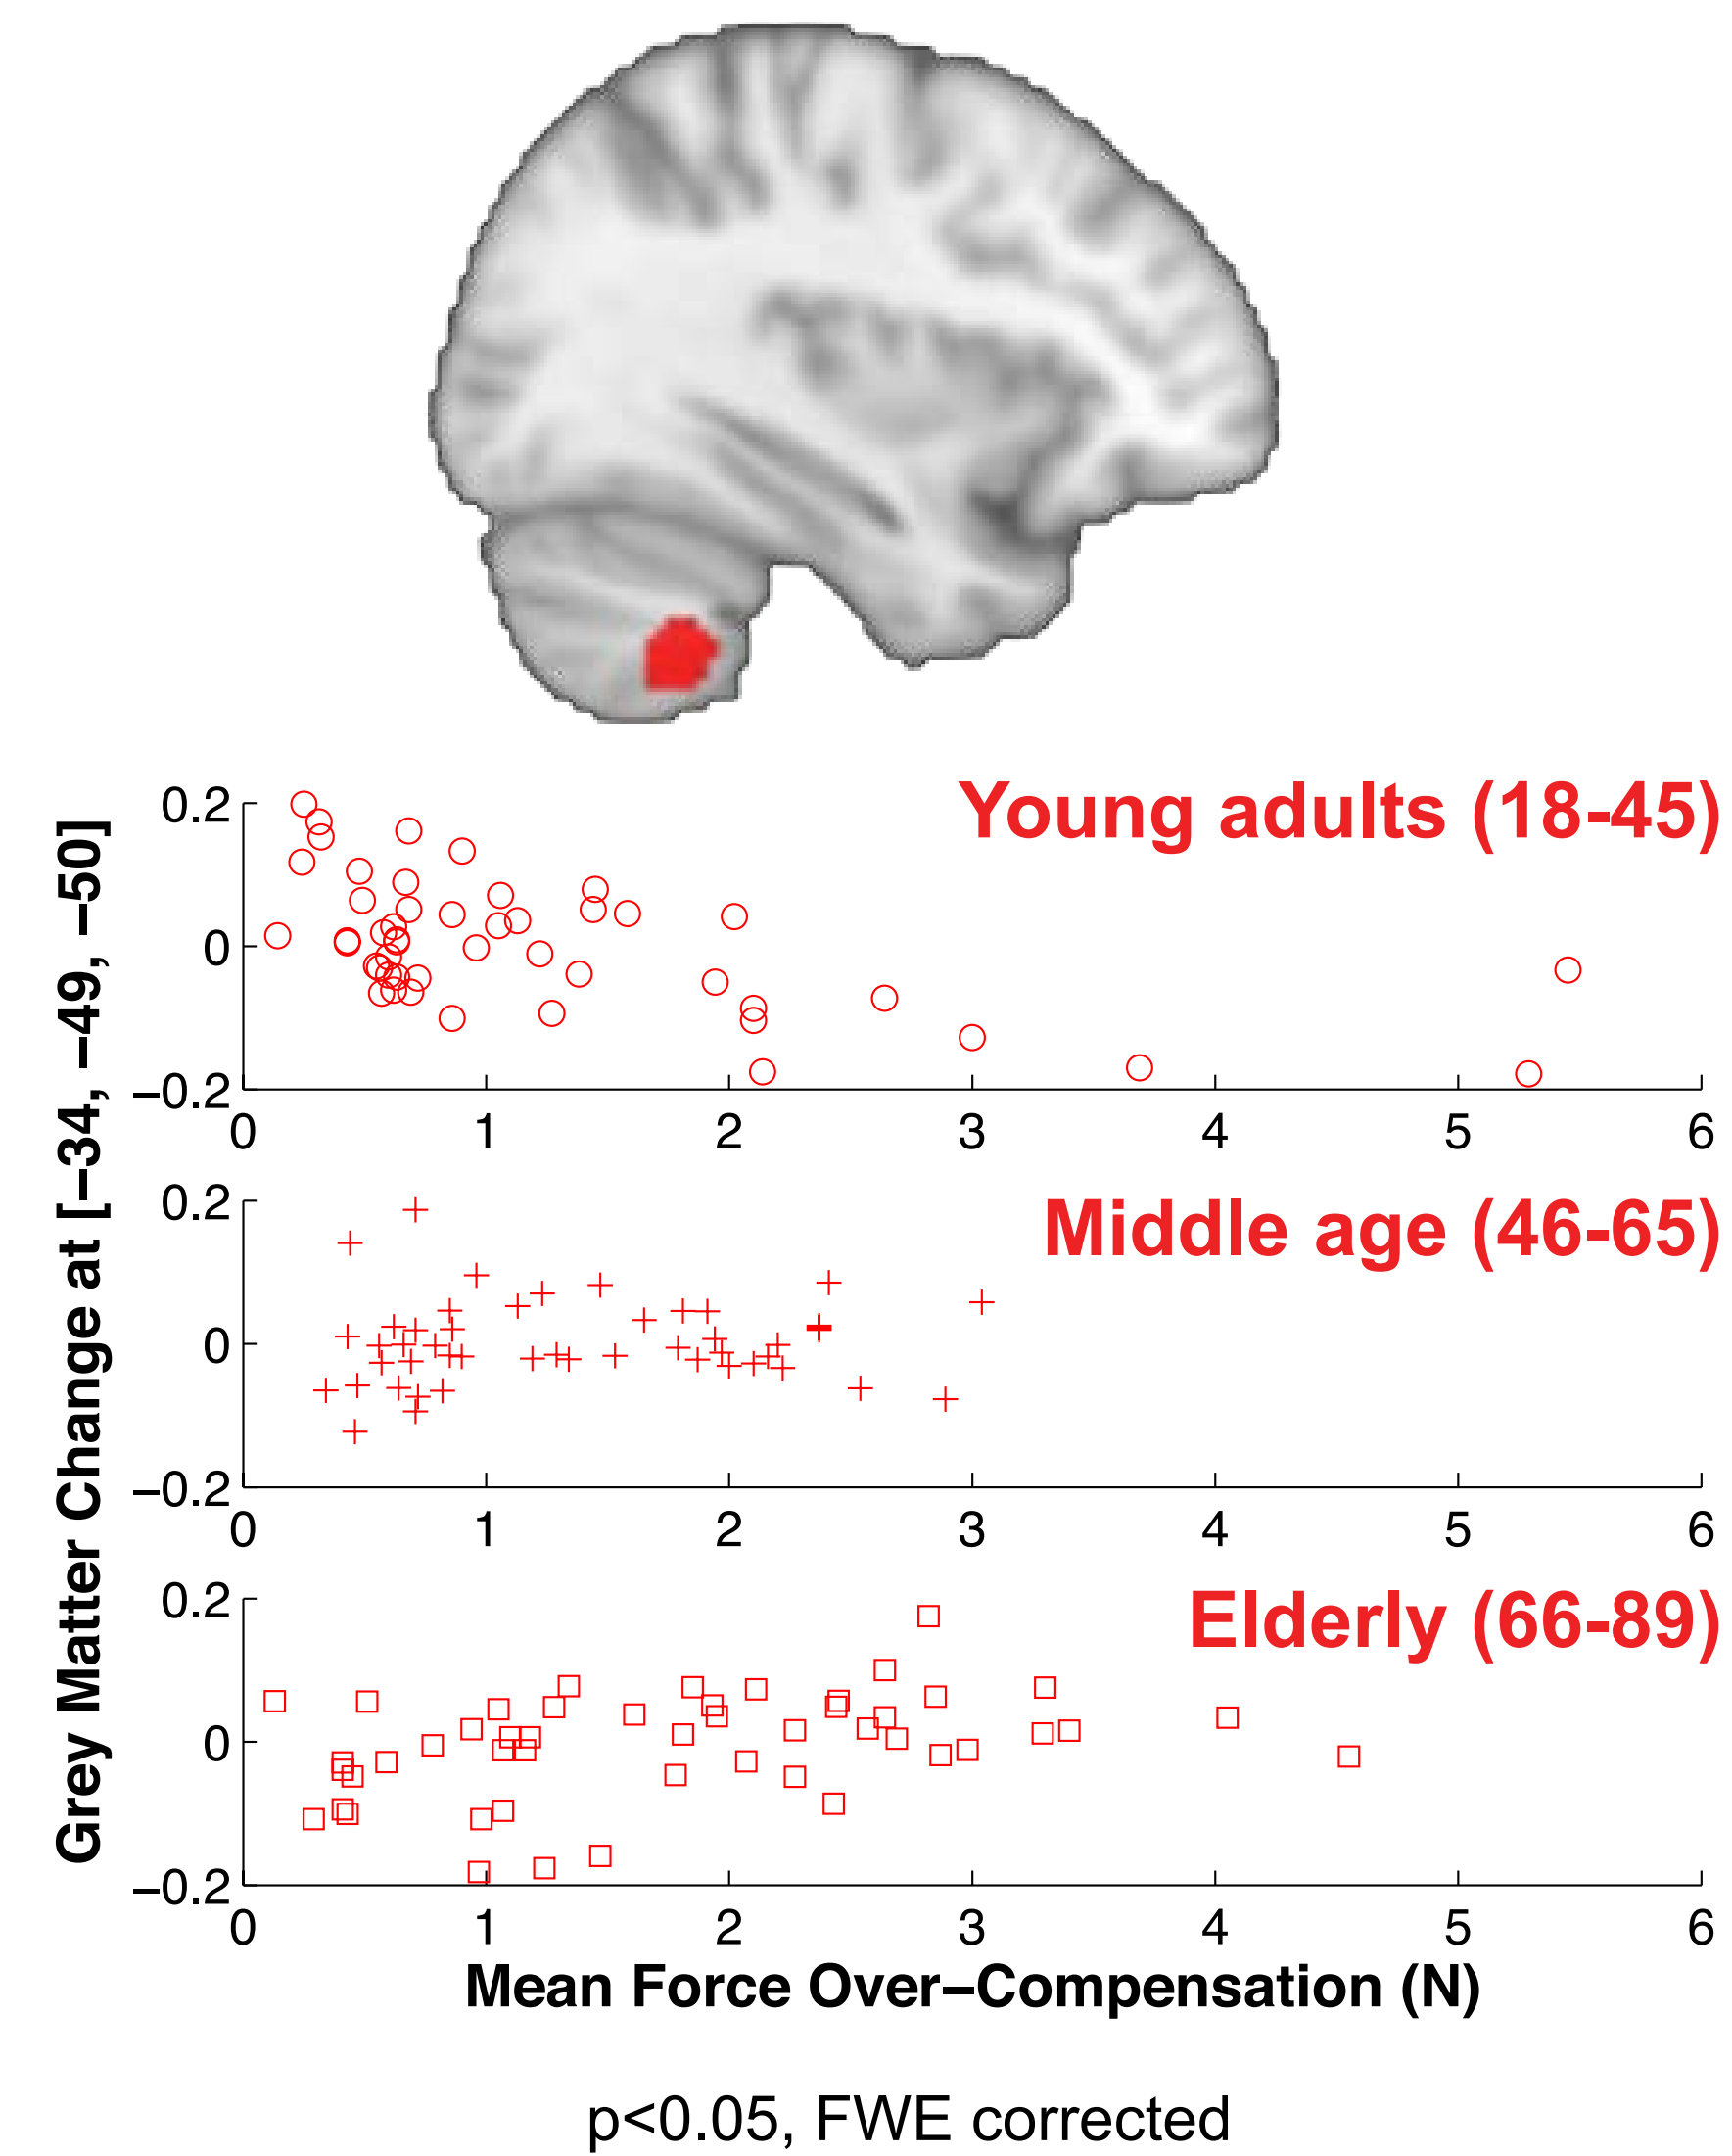

Association with grey matter

Negative correlation between force over-compensation in the Direct condition and grey matter volume in the premotor cortex, SMA, pre-SMA, bilateral insula, operculum and precuneus

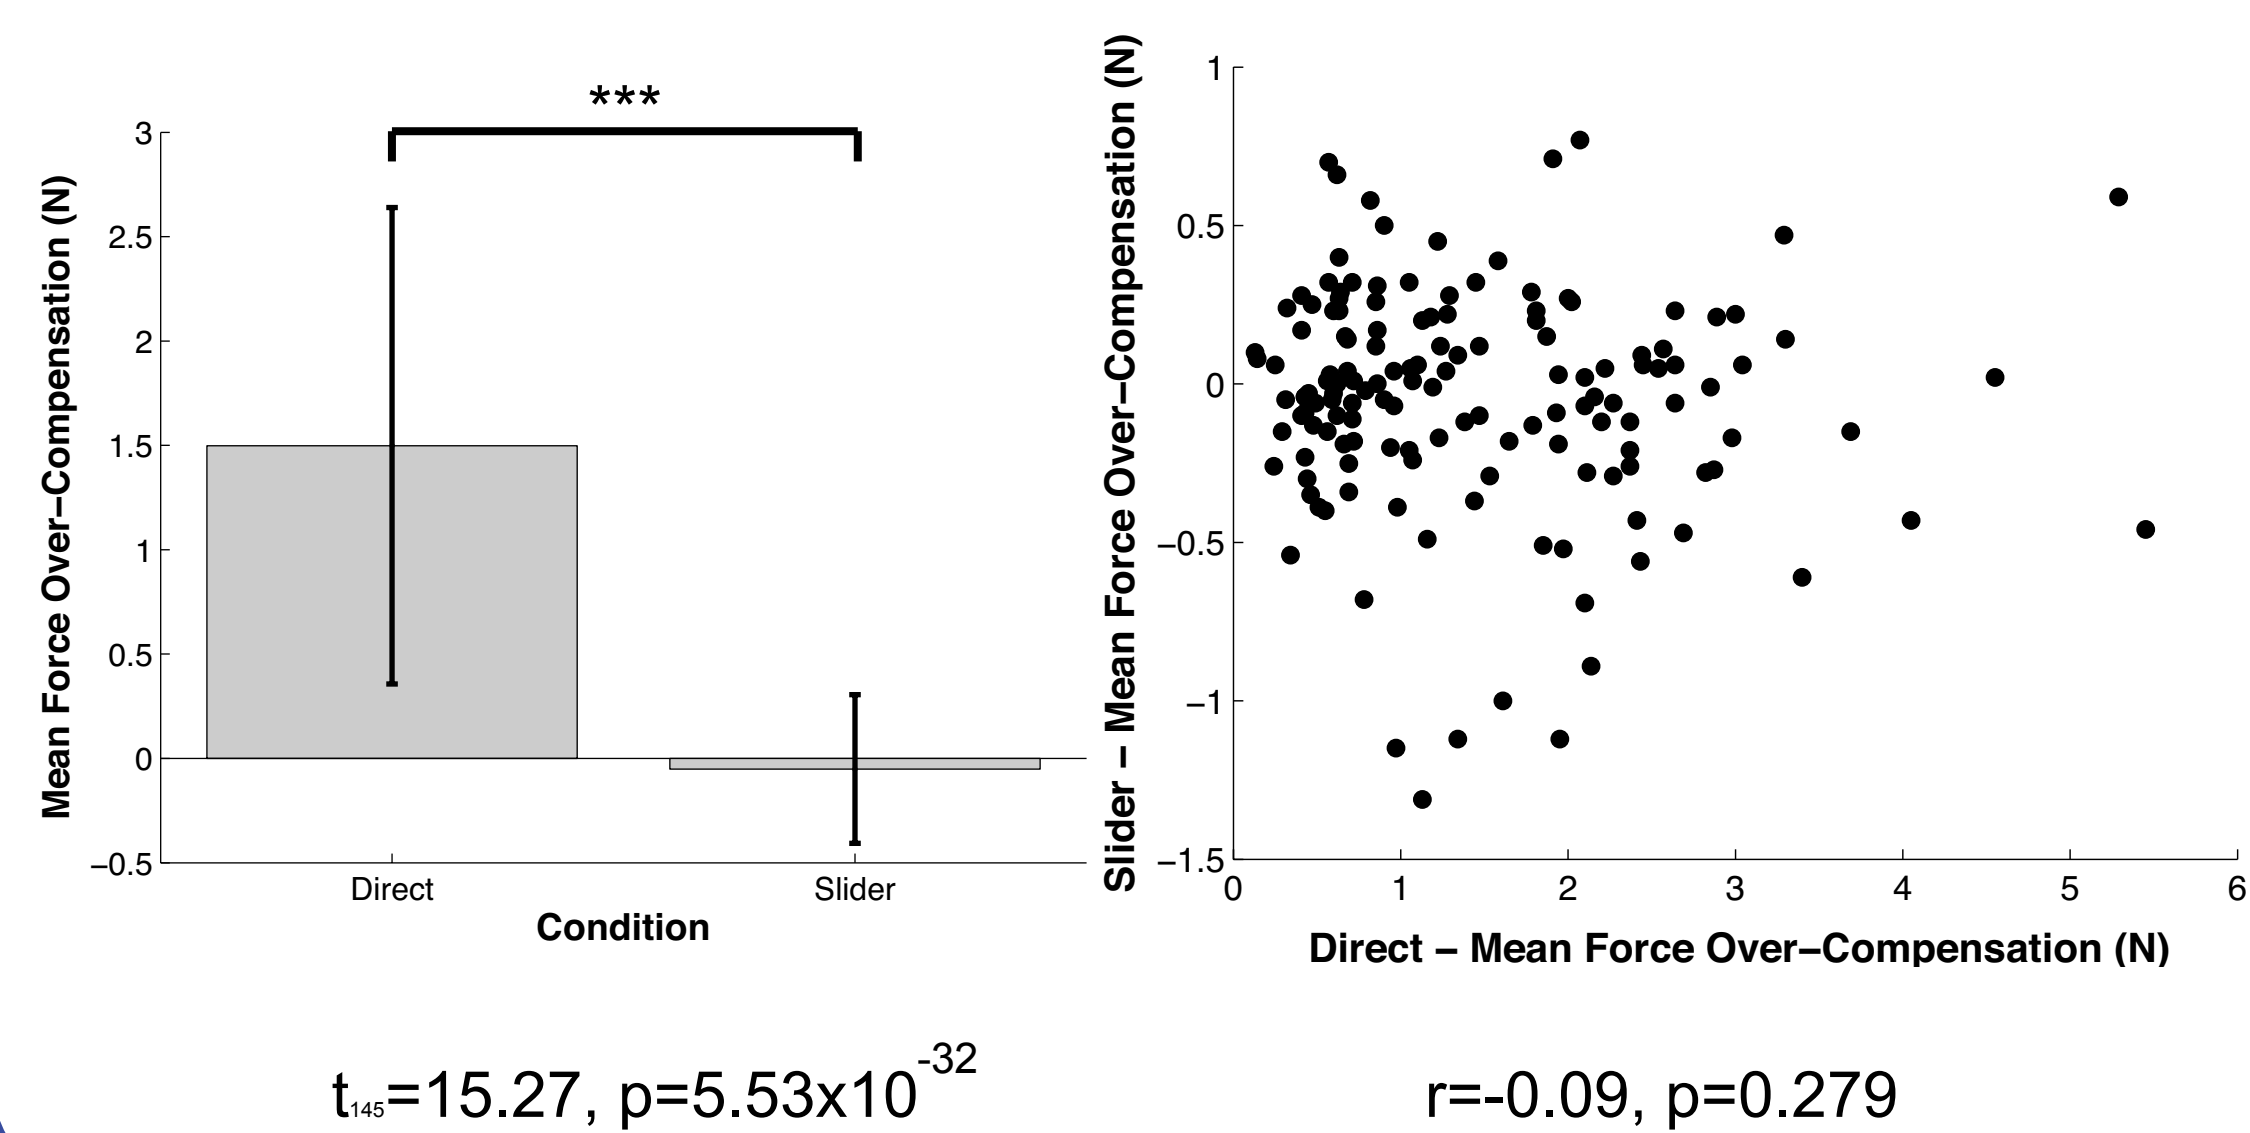

Age-dependent association

Positive interaction between Direct force over-compensation and grey matter volume in the cerebellum

Group mean over-compensation

Conclusions

- The areas associated with sensorimotor attenuation, particularly the pre-SMA and insula, are repeatedly implicated in preparation for voluntary movement and awareness of action.
- The cerebellum is proposed to generate forward models, and compare predicted and actual sensory feedback.
- The results support previous accounts that the pre-SMA and insular cortex process efference copies of motor commands.
- Cerebellar contribution to sensorimotor attenuation is changed with age, possibly due to the differential effects of ageing on the cerebellum and cortex.
